

Chapter 1

Spectrometer systems for radio astronomy

Danny C. Price, Jack Hickish and Dan Werthimer

Campbell Hall 339, UC Berkeley

Address goes here,

dancpr@berkeley.edu

This review gives an introduction to spectrometers and discusses their use within radio astronomy. While a variety of technologies are introduced, particular emphasis is given to digital systems, with details of current-generation implementations given as examples. Three different types of digital spectrometers are discussed: autocorrelation spectrometers (ACS), Fourier transform spectrometers (FTF, Sec. 3.2), and polyphase filterbank spectrometers (PFB). Given their growing ubiquity, polyphase filterbanks are detailed at length. The relative advantages and disadvantages of spectrometer technology are compared and contrasted, and implementation considerations are presented.

1. Introduction

A *spectrometer* is a device used to record and measure the spectral content of signals, such as radio waves received from astronomical sources. Specifically, a spectrometer measures the power spectral density (PSD, measured in units of WHz^{-1}) of a signal. Analysis of spectral content can reveal details of radio sources, as well as properties of the intervening medium. For example, spectral line emission from simple molecules such as neutral hydrogen gives rise to narrowband radio signals (Fig. 1), while continuum emission from active galactic nuclei gives rise to wideband signals.

There are two main ways in which the PSD — commonly known as *power spectrum* — of a signal may be computed. The power spectrum, S_{xx} , of a waveform and its autocorrelation function, r_{xx} , are related by the Wiener-Khinchin theorem. This theorem states that the relationship between a stationary (mean and variance do not change over time), ergodic (well-behaved over time) signal $x(t)$, its PSD, and its autocorrelation is given by

$$S_{xx}(\nu) = \int_{-\infty}^{\infty} r_{xx}(\tau) e^{-2\pi i \nu \tau} d\tau. \quad (1)$$

where ν represents frequency, and τ represents a time delay or ‘lag’. The autocor-

Fig. 1.: A galactic hydrogen 21-cm line emission profile, as measured using a digital spectrometer system on the Robert C. Byrd Greenbank Telescope in West Virginia.

relation function is

$$r_{xx}(\tau) = \langle x(t)x(t - \tau) \rangle, \quad (2)$$

where angled brackets refer to averaging over time.

Equation 1 shows that the autocorrelation function is related to the PSD by a Fourier transform. In the discrete case, the relationship becomes

$$S_{xx}(k) = \sum_{n=-\infty}^{\infty} \langle x(n)x(n - k) \rangle e^{-2\pi i k \tau}, \quad (3)$$

which may be recognized as a discrete convolution. It follows from the convolution theorem that

$$S_{xx}(k) = \langle |X(k)|^2 \rangle, \quad (4)$$

where $X(k)$ denotes the Discrete Fourier Transform (DFT) of $x(t)$:

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-2\pi i n k / N} \quad (5)$$

There are therefore two distinct classes of spectrometers: ones that approximate $S_{xx}(k)$ by firstly forming the autocorrelation, then taking a Fourier transform ala Eq. 3, and those that first convert into the frequency domain to form $X(k)$ before evaluating Eq. 4. We will refer to these as autocorrelation spectrometers (ACS, Sec. 3.1), and Fourier transform filterbanks (FTF, Sec. 3.2), respectively. Polyphase filterbank spectrometers (PFB, Sec. 3.3) can be thought of as an FTF with enhanced filter response.

1.1. Analysis and synthesis filterbanks

It is important to note the relationship between spectrometers, filters, and filterbanks. A *filterbank* is simply an array of band-pass filters, designed to split an input signal into multiple components, or similarly, to combine multiple components. These are referred to as *analysis* and *synthesis* filterbanks, respectively. When applied to streaming data, a DFT can be considered an analysis filterbank, and an inverse DFT to be a synthesis filterbank; we return to this in XX. From this viewpoint, a spectrometer is simply an analysis filterbank, where the output of each filter is squared and averaged.

Analysis and synthesis filterbanks have many applications outside of astronomy, see [REF] for further discussion.

1.2. Polarimetry

Polarization¹³ is a key measurement within radio astronomy. Although most astrophysical radio emission is inherently unpolarized, a number of radio sources — such as pulsars and masers — do emit polarized radiation, and effects such as Faraday rotation by a galactic magnetic fields can yield polarized signals. A spectrometer that also measures polarization is known as a *polarimeter* (or spectropolarimeter).

1.2.1. Stokes parameters

The Stokes parameters are a set of four quantities which fully describe the polarization state of an electromagnetic wave; this is what a polarimeter must measure. The four Stokes parameters, I , Q , U and V , are related to the amplitudes of perpendicular components of the electric field:

$$E_x = e_x(t)\cos(\omega t + \delta_x) \quad (6)$$

$$E_y = e_y(t)\cos(\omega t + \delta_y) \quad (7)$$

by time averages of the electric field parameters:

$$I = \langle E_x E_x^* + E_y E_y^* \rangle \quad (8)$$

$$Q = \langle E_x E_x^* - E_y E_y^* \rangle \quad (9)$$

$$U = \langle E_x E_y^* + E_y E_x^* \rangle \quad (10)$$

$$V = i \langle E_x E_y^* - E_y E_x^* \rangle \quad (11)$$

where $*$ represents conjugation. The parameter I is a measure of the total power in the wave, Q and U represent the linearly polarised components, and V represents the circularly polarised component. The Stokes parameters have the dimensions of flux density, and they combine additively for independent waves.

1.2.2. Measuring polarization products

In order to compute polarization products, a spectrometer must be presented with two voltage signals, $x(t)$ and $y(t)$, from a dual-polarization feed (i.e. a set of orthogonal antennas). With analogy to Eq. 4, we may form

$$S_{xx}(k) = \langle X(k)X^*(k) \rangle = \langle |X(k)|^2 \rangle \quad (12)$$

$$S_{yy}(k) = \langle Y(k)Y^*(k) \rangle = \langle |Y(k)|^2 \rangle \quad (13)$$

$$S_{xy}(k) = \langle X(k)Y^*(k) \rangle \quad (14)$$

$$S_{yx}(k) = \langle Y(k)X^*(k) \rangle \quad (15)$$

where in addition to measuring the PSD of $x(t)$ and $y(t)$, we also compute their cross correlations. Note that while S_{xx} and S_{yy} are real valued, S_{xy} and S_{yx} are complex valued.

The four terms $\langle E_x E_x^* \rangle$, $\langle E_y E_y^* \rangle$, $\langle E_x E_y^* \rangle$, and $\langle E_y E_x^* \rangle$ are linearly related (by calibration factors) to the quantities in Eq. 12-15 above. Combining these therefore allows for Stokes I , Q , U and V to be determined.

In order to focus on the fundamental characteristics of spectrometers, the remainder of this chapter details single-polarization systems that compute only S_{xx} . Nevertheless, the techniques and characterization approaches are broadly applicable to polarimetry systems.

1.3. Performance characteristics

There are several important characteristics to consider when comparing spectrometer implementations. Spectrometers operate over a finite bandwidth B , over which N channels with bandwidth $\Delta\nu = B/N$ are computed. With digital filters, it is possible for each channel to be evenly spaced and to have identical filter shapes.

Ideally, each channel would have unitary response over $\nu_c \pm \frac{\Delta\nu}{2}$, where ν_c is the center frequency, with zero response outside this passband. In practice, this cannot be achieved; each channel has a non-zero response over all frequencies. Fig. 2 compares the normalized filter response for ACS, FTF and PFB implementations. As such, a signal will ‘leak’ between neighboring channels, known as *spectral leakage*. In the presence of strong narrowband signals, such as radio interference (RFI), spectral leakage is a major concern.

A related concern is that the channel’s non-ideal shape will cause narrowband signals at channel edges to be attenuated, an effect known as scalloping loss (Fig. 3). Spectrometers are often designed such that neighboring channels overlap at their full-width at half-maximum points (FWHM), in which case the signal will be spread evenly over both channels. Wideband signals are not affected by scalloping.

Two other important factors are 1) the minimum and maximum integration times, t_{\min} and t_{\max} , over which a spectrometer may operate, and 2) the dynamic range (DR), the span of powers over which a spectrometer can operate nominally. These factors are generally enforced by hardware limitations. Detection of transient

Fig. 2.: Comparison of the filter response of a, ACS (dotted line), FTF (dashed line) and an 8-tap, Hann-windowed PFB (solid line).

phenomena, such as fast radio bursts (FRBs [REF]) and pulsars, require t_{\min} to be as short as a nanosecond. The presence of RFI is often the main driver for dynamic range; see Sec. 2.1.2.

For implementation on current technology, PFB spectrometers offer the least scalloping loss and spectral leakage, so are in most instances preferable to FTF and ACS implementations. A comparison of architectures is given in 3.4.

2. Digital systems

Digital signal processing (DSP) techniques are well-suited to applications such as filtering and forming filterbanks; as such, a majority of current-day spectrometers are based on digital technology. This section gives a short overview of DSP techniques; I refer the reader unfamiliar with digital signal processing to the excellent[?] and.[?]

In the diagrams and equations that follow, the symbol \otimes denotes multiplication of time samples, and \oplus denotes addition. The symbol z^{-n} is used to denote a time delay of n units, and the symbol $\downarrow D$ is used for downsampling by a factor D and $\uparrow U$ for upsampling by a factor U .

Fig. 3.: Example of scalloping loss between spectrometer channels. The dashed lines show the response of individual channels, while the black line shows the overall response.

2.1. Digital sampling

Digital sampling, or *digitization*, is the process of converting an analog signal to a digital one. As their name implies, analog to digital converters (ADCs) do this conversion. The two main characteristics of an ADC are its sample rate, ν_s , and the number of bits per sample, N_b .

The ADC converts an analog voltage waveform into a series of numeric quantities called *samples*. The sample rate determines the amount of bandwidth that can be unambiguously processed by an ADC. The Nyquist Theorem — one of the most fundamental theorems within signal processing — states that a band-limited signal may be fully recovered when it is sampled at a rate that is twice the bandwidth, $\nu_s = 2B$. Sampling at the Nyquist rate is referred to as *critical sampling*, under the Nyquist rate as *undersampling*, and sampling over the Nyquist rate as *oversampling*.

Undersampling a signal causes an effect known as *aliasing* to occur, whereby different parts of a signal are indistinguishable from each other, resulting in information loss. Note that oversampling a signal does not increase the information content, but under certain circumstances is advantageous for reducing noise and/or distortion.

2.1.1. Quantization efficiency

The earliest digital correlators¹⁶ used only two-level sampling (one bit), assigning a value of either +1 or -1. This scheme works remarkably well for weak, noise-dominated signals^a: for Nyquist-sampled signals, a signal-to-noise ratio of $2/\pi =$

^aThat is, we assume that the probability distribution of the signal is close to Gaussian.

Table 1.: Quantization efficiencies η_Q for Nyquist sampling with different bit depths N_{bits} . Table modified from Thompson et. al.¹¹

N_{bits}	N_{levels}	ε	η_Q
2	4	0.995	0.88115
3	8	0.586	0.96256
4	16	0.335	0.98846
5	32	0.188	0.99651
6	64	0.104	0.99896
7	128	0.0573	0.99970
8	256	0.0312	0.99991

0.637 that of the unquantized signal is achievable [REF VAN VLECK 1966] (see Chapter 8 of TMS¹²). For 2-bit data, one can achieve 88% quantization efficiency, which rises to 98% for 4-bit data. Given these high values for low bit-widths, it is common to use bits sparingly within radio astronomy applications. A listing of quantization efficiencies¹¹ is given in Table 1.

Achieving peak quantization efficiency relies on setting the threshold between quantized values optimally. In Table 1, the threshold ε is expressed in units of the signal's standard deviation σ . In order to leave headroom for interfering signals, one may deliberately set ε larger than that optimal for signals with Gaussian probabilities to increase dynamic range.

2.1.2. Dynamic range

For modern-day radio environments, RFI is the main driver of sampling bitwidth. RFI may be orders of magnitude stronger than an astronomical signal of interest, requiring a large dynamic range in the digitized waveform. If the maximum input power to an ADC is exceeded, an effect known as *clipping* will occur, in which the waveform is distorted and spurious harmonics are introduced into the digitized waveform.

The theoretical maximum dynamic range of an ADC in decibels is given by

$$DR = 20 \log_{10}(2^{N_{\text{bits}}}) \approx 6.02 N_{\text{bits}} \quad (16)$$

in practice, as ADCs are imperfect analog devices, their effective number of bits (ENOB) is below this. For example, an 8-bit ADC may have an ENOB of 7.5, resulting in a dynamic range of 45 dB.

2.2. Windowing functions

The DFT is computed over a finite number of samples, N , also known as the *window length*. As the window length is not infinite, the response of the DFT is not perfect,

resulting in spectral leakage (Fig. 2). This can be understood if we consider that the DFT

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-2\pi ink/N} \quad (17)$$

$$= \sum_{n=-\infty}^{\infty} \Pi(n)x(n)e^{-2\pi ink/N} \quad (18)$$

$$= \mathcal{F}\{\Pi(n)\} * X'(k) \quad (19)$$

where \mathcal{F} denotes the Fourier transform, and $\Pi(n)$ the rectangle (or tophat) function:

$$\Pi(n) = \begin{cases} 0 & \text{if } n < 0 \\ 1 & \text{if } 0 \leq n \leq N-1 \\ 0 & \text{if } n > N-1, \end{cases} \quad (20)$$

which is Fourier paired with the $\text{sinc}()$ function^b. In other words, we can consider the finite length of the DFT as effectively convolving the perfect Fourier transform response $X'(k)$ with a sinc function. The undesirable peaks of the sinc function are referred to as *sidelobes*.

Windowing functions⁷ improve the response of a DFT, by somewhat mitigating sidelobe response, at the expense of increasing the channel width. They are applied by multiplying the signal $x(n)$ by a weighting function, $w(n)$:

$$X_w(k) = \sum_{n=0}^{N-1} w(n)x(n)e^{-2\pi ink/N} \quad (21)$$

$$= W(k) * X(k). \quad (22)$$

The take-home message of all this is that DFT channels have a non-zero response outside their passband (Fig. 4), and that applying a windowing function can improve their response.

Windowing functions are also important in the design of digital filters (Sec. 2.6). Some common windowing functions and their frequency-domain magnitude responses are shown in Fig. 5; their functional forms are given in Tab. 2. The most appropriate windowing function is dependent upon application; for digital spectrometers, the Hamming and Hann windows are commonly applied.

A more dramatic improvement may be achieved by using an lowpass filter front-end before the DFT,¹ to form what is known as a polyphase filterbank. This approach is detailed further Sec. 3.3.

2.3. Digital mixing and quadrature sampling

A common DSP task is to take a band-limited signal centered at a frequency ν_c and ‘mix’ it down to baseband [EQN HERE]. Very brief intro to IF mixing, just required $e^{i\omega t}$ to be introduced for lowpass \rightarrow bandpass. [JACK MAYBE?]

^bThis is the same relationship as that between light passing through a single slit aperture and its far-field diffraction pattern

Fig. 4.: Amplitude response of the DFT, compared to amplitude response of a Hann-windowed DFT.

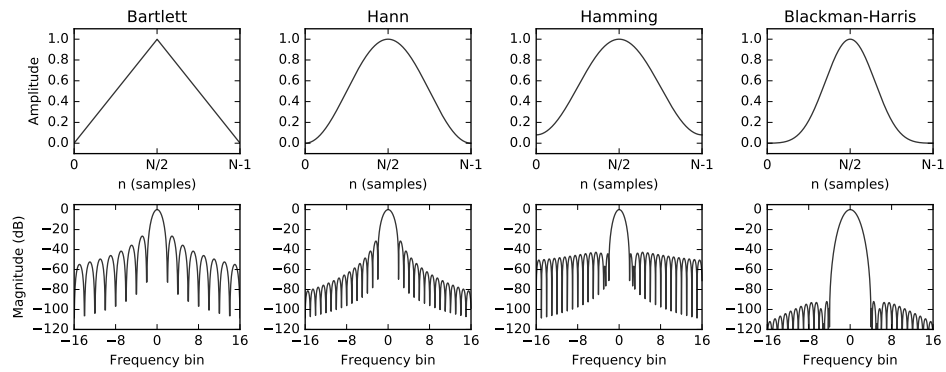

Fig. 5.: Four common windowing functions ($w(n)$, top) and their corresponding squared Fourier transforms ($|W(k)|^2$, bottom). Outside of the range $[0, N - 1]$, the function $w(n) = 0$ for all windows.

Also need to introduce the term **quadrature** for complex sampling, state that Nyquist rate is not broken.

2.4. Sample rate conversion

Upsampling and downsampling.

Table 2.: Some common windowing functions, used in digital filters and DFT filterbanks. Note that in this table, coefficients have been rounded to four significant digits.

Weighting function	$w(n)$
Uniform (rectangular)	1
Bartlett (triangular)	$1 - (n /(N - 1))$
<i>General form:</i>	$a_0 - a_1 \cos(\frac{2\pi n}{N-1})$
Hann	$a_0 = 0.50 \quad a_1 = 0.50$
Hamming	$a_0 = 0.54 \quad a_1 = 0.46$
<i>General form:</i>	$a_0 - a_1 \cos(\frac{2\pi n}{N-1}) + a_2 \cos(\frac{4\pi n}{N-1}) - a_3 \cos(\frac{6\pi n}{N-1})$
Nuttall	$a_0 = 0.3558 \quad a_1 = 0.4874 \quad a_2 = 0.1442 \quad a_3 = 0.0126$
Blackman-Nuttall	$a_0 = 0.3636 \quad a_1 = 0.4892 \quad a_2 = 0.1366 \quad a_3 = 0.0106$
Blackman-Harris	$a_0 = 0.3588 \quad a_1 = 0.4883 \quad a_2 = 0.1413 \quad a_3 = 0.0117$

2.5. The z-transform

This is something I don't understand properly myself. Jack to explain why z-transform = delay?

2.6. Finite impulse response filters

Fig. 6.: N-tap FIR filter block diagram. An FIR filter applies a weighted sum to the input sequence $x(t)$, outputting the filtered signal $y(t)$.

A finite impulse response (FIR) filter is the windowed moving average of an input sequence $x(t)$. An FIR filter computes the sum

$$y(t) = \sum_{k=0}^{K-1} h(k)x(t-k), \quad (23)$$

where $y(n)$ is the output sequence, and $h(k)$ is a set of K coefficients used for weighting. The upper summation bound, K , is called the number of taps. A streaming implementation of an FIR filter is shown in Figure ??.

If we downsample after an FIR by $\downarrow D$, we only keep the outputs $t = mD$, $m \in \mathbb{Z}^+$. A $\downarrow D$ downsampled filter will alias spectra centred at any multiple of the output sample rate to baseband. In such cases it is more efficient to only compute the terms we wish to keep:

$$y(mD) = \sum_{k=0}^{K-1} h(k)x(mD - k). \quad (24)$$

One way we can accomplish this is to use a polyphase decimating filter, which is discussed below.

2.7. Polyphase FIR filters

Fig. 7.: Example illustrating the polyphase decomposition of the coefficients $h(k)$ of a 64-tap FIR filter (left) into 8 sub-filters (right). Each sub-filter has 8 taps; that is, $P=8$ and $M=8$. These sub-filters may be re-combined in a suitable polyphase filter structure to form a filter with an impulse response equal to the original FIR filter (left).

A common technique in DSP is to decompose an input sequence $x(t)$ into a set

$$\mathbb{P} = \{x_k(t) \mid k \in (0, P-1)\} \quad (25)$$

of P sub-sequences, $x_k(t)$, each of which is given by

$$x_k(t) = (\downarrow P)(z^{-k})x(t). \quad (26)$$

This is known as polyphase decomposition. Even and odd decomposition of the signal $x(t)$ is achieved when $P = 2$:

$$x_0(t) = \{x(0), x(2), x(4), \dots\} \quad (27)$$

$$x_1(t) = \{x(1), x(3), x(5), \dots\}. \quad (28)$$

More generally, an input stream may be decomposed into P different ‘phases’.

Polyphase filter structures are often more efficient than standard finite impulse response filters when used in sample rate conversion. A $\downarrow P$ decimating FIR filter of length $K = MP$ can be constructed from P discrete FIR filter ‘branches’, each acting upon a different phase; that is

$$y(t) = \sum_{p=0}^{P-1} \sum_{m=0}^{M-1} h_p(m) x_p(t-m), \quad (29)$$

This is known as a decimating polyphase filter. For example, a $P = 4$ branch polyphase filter with $M = 7$ taps per sub-filter would compute the sum

$$\begin{aligned} y(t) = & \sum_{m=0}^7 h_0(m) x_0(t-m) + \sum_{m=0}^7 h_1(m) x_1(t-m) \\ & + \sum_{m=0}^7 h_2(m) x_2(t-m) + \sum_{m=0}^7 h_3(m) x_3(t-m), \end{aligned} \quad (30)$$

and has an output equivalent to a $4 \times 7 = 28$ tap standard FIR filter with 4:1 downsampling.

Decimating polyphase filter structures are more efficient than standard FIR filter based downsampling techniques. If $\downarrow D$ downsampling occurs after the moving average of Equation 23, we compute D sums, but keep only 1 in D of these. This is inefficient. In comparison, Equation 29 only computes the output values that are of interest.

A comprehensive overview of polyphase filters is given by Vaidyanathan,¹⁴ and in Chapter 2 of Harris;⁷ I will give a brief introduction here.

2.8. The Fast Fourier Transform

* Radix 2 stuff

3. Digital spectrometers

The first digital spectrometer used for radio astronomy was developed by Weinreb¹⁶ in 1963. This 1-bit ACS was used to observe the 18-cm wavelength hydroxyl (OH) absorption line in the spectrum of Cassiopeia A, providing the first evidence of OH in the interstellar medium.¹⁵ The first reference to FTF spectrometers for radio astronomy can be found in;⁴ however FTF spectrometers did not enjoy widespread adoption until much later. This is due to implementation issues, such as increased

data output rates as compared to ACS implementations; see,³ for a discussion of these issues.

The first class are called lag-autocorrelators, or auto-correlation spectrometers (ACS). The second class are known as Fourier transform filterbanks (FTF).

There are two distinct classes of digital spectrometers: ones that approximate $S_{xx}(k)$ through numerical approximation to Equation 3, and those that evaluate Equation 4. The first class are called lag-autocorrelators, or auto-correlation spectrometers (ACS). The second class are known as a discrete Fourier transform filterbanks (FTF).

3.1. Autocorrelation spectrometers

Regardless of autocorrelator implementation, it is invariably the case that Equation ?? is computed for only a discrete range of delays, τ . In much the same way as the sampling rate of an analog signal determines how much bandwidth can be processed unambiguously (see Section ??) the spacing of lags in an autocorrelator determines how much bandwidth it can process without aliasing occurring. In the case of an autocorrelator the Nyquist criterion is satisfied when there are two taps per wave period at the highest frequency (shortest wavelength) signal of interest.

Digital autocorrelators implement the autocorrelators delay-and-multiply circuitry using digital delays – shift registers – and digital multiplier cores to compute signal products. As a result, digital correlators can have much more predictable performance than their analog counterparts whose processing is subject to small errors in delay line lengths and other subtle analog effects. In contrast, provided signals in a digital autocorrelator can be digitised with adequate signal-to-noise and linearity the downstream autocorrelation computation can be regarded as possessing perfect precision.

Digital systems are usually preferred when the bandwidth to be processed is within the capabilities of commercially available ADC chips. However, if the number of frequency channels desired is large an FFT-based spectrometer may be preferable to an autocorrelation system. FFT spectrometers are described more fully in Section ?? and can be implemented with vastly lower computational overhead, at the cost of increased design complexity.

3.2. Fourier transform spectrometers

A time-domain signal $v(t)$ may be spectrally decomposed using a Fourier Transform, defined by:

$$V(f) = \int_{-\infty}^{\infty} v(t)e^{-2\pi if} dt. \quad (31)$$

In a digital system, where an input has been discretely sampled N times with values v_n the Fourier Transform may be reduced to its discrete form:

$$V_f = \sum_{n=0}^{N-1} v_n e^{\frac{-2\pi i f n}{N}} \quad f = [0, N-1]. \quad (32)$$

Equation 32 may be thought of as the mixing of the input signal with a bank of oscillators, followed by an averaging with a square window function. In effect, this is a simple filterbank.

In general, computing Equation 32 for each value of f requires N multiplications, and N additions. Since f can take N independent values itself, the total cost of implementing a DFT filterbank is N^2 operations per transform. If one transform is computed for every N samples digitized, then the computation rate is of order $F_s N$ operations each second, where F_s is the sampling rate.

In the case that samples v_n are regularly spaced in time (which they almost invariably are) the Fast Fourier Transform (FFT,⁵) algorithm allows Equation 32 to be evaluated in $O(N \log_2(N))$ operations, or $F_s \log_2(N)$ if performed every N samples. With computational savings of order $N/\log 2N$ the FFT is an extraordinarily powerful algorithm, which is used heavily throughout radio astronomy. For a spectrometer of 10^4 channels, the FFT algorithm requires approximately 0.1% as many operations as an autocorrelation spectrometer.

3.3. Polyphase filterbanks

In comparison to both ACS and FTF architectures, polyphase filterbanks offer vastly improved interchannel isolation. For radio astronomy purposes, high interchannel isolation is important so that spectral features are not smeared out, and so the spectrometer is more resilient to the high levels of radio frequency interference (RFI) emitted from terrestrial sources. Polyphase filterbanks are therefore the best candidate for radio astronomy spectrometers, if computationally affordable.

A computationally efficient filterbank with high interchannel isolation can be constructed from an FFT preceded by a prototype polyphase FIR filter frontend. Such an implementation exploits the fact that a lowpass filter with coefficients $h(k)$, can be converted into a quadrature (complex) bandpass filter with central frequency ω_k by multiplying the coefficients by $e^{i\omega_k t}$. That is,

$$h_{bpf}(k) = h(k)e^{i\omega_k t}. \quad (33)$$

Now, suppose we have a decimating lowpass polyphase filter, such as that in Figure ???. The output of each branch is

$$y_p(t) = \sum_{m=0}^{M-1} h_p(m)x_p(t-m), \quad (34)$$

where $h_p(m)$ are coefficients from our prototype lowpass filter. If we follow this by

a DFT, as in Figure ??, we then have

$$Y(k) = \sum_{p=0}^{P-1} y_p(t) e^{-2\pi i k p / P} \quad (35)$$

$$= \sum_{p=0}^{P-1} \sum_{m=0}^{M-1} h_p(m) e^{-2\pi i k p / P} x_p(t - m). \quad (36)$$

Comparing this form to Equation 24 and Equation 33, we recognise that the output of this structure — Figure ?? — is equivalent to a set of $\downarrow P$ downsampling polyphase filters:

$$\mathbb{F} = \{h_k(m), k \in (0, P - 1)\} \quad (37)$$

where the central frequency of each filter is shifted by an amount $2\pi i k / P$. For data sampled at the Nyquist rate f_s , this filterbank consists of N filters spanning $-f_s/2$ to $f_s/2$, with each filter separated by $f_s/2N$. For real sampled data the negative frequencies contain no extra information, so they need not be computed. This leaves a bank of $N/2$ filters, evenly spaced over a bandwidth $f_s/2$. This is the structure that I have implemented.

This polyphase filterbank (PFB) structure was first proposed by,¹ and has been previously used in radio astronomy applications, see for example¹⁷ and.⁹ The rest of this chapter discusses the implementation of a 8192 channel polyphase filterbank for radio astronomy, on Field Programmable Gate Array based digital hardware.

3.3.1. Overlapping filterbanks

3.4. Implementation comparison

ACS and FTF architectures differ in both their spectral response and the number of computations required to implement them. For regularly sampled data, the Fast Fourier Transform (FFT) algorithm may be used to compute the DFT (see, for example,²), which reduces the number of computations required from $O(N^2)$ for to $O(N \log(N))$. In Chapter 4 of,¹⁰ Romney shows that the ratio of multiplies for the two architectures is

$$R_{\frac{ACS}{FTF}} = \frac{n_t}{2 \log_2(n_t)}, \quad (38)$$

where n_t is the number of samples per FFT or lag correlation. So in general, FTF architectures require fewer computations than their equivalent ACS counterpart. Romney also shows that the spectral response of FTF and ACS architectures differ, with ACS architectures having a *sinc* response, and FTF architectures possessing a *sinc*² response. The result is that interchannel isolation is better in FTF architectures (first sidelobe at ~ -13.6 dB), than in ACS architectures (~ -6.8 dB).

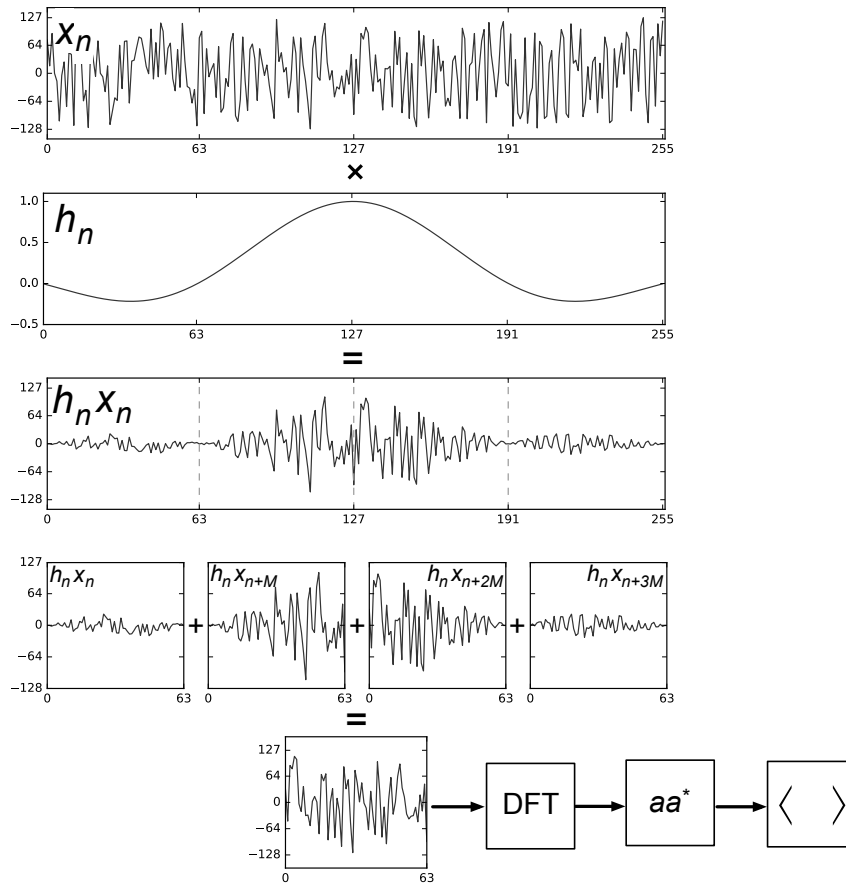

Fig. 8.

3.5. Zoom modes

4. Alternative spectrometer implementations

4.1. Swept spectrometer

A *swept spectrometer* uses a variable oscillator with a heterodyne circuit and a low pass filter. The oscillator is typically varied, i.e. swept, through a range of desired frequencies. As it is swept through the desired frequency range, the power of the low pass filter's output is measured and recorded. Most analog spectrum analyzers operate in this manner.

An advantage of swept spectrometers is that they can operate over large RF bandwidths. However, as only a fraction of the band is detected at any one time,

Fig. 9.: Polyphase filterbank streaming implementation.

less integration time is available per frequency channel. For a swept spectrometer with N channels with a sweep time of t_{sweep} , the integration time available per channel is t_{sweep}/N . It follows that the RMS noise per channel is \sqrt{N} higher than an equivalent filterbank spectrometer covering the entire RF bandwidth. As such, swept spectrometers are best suited for cases where signals of interest are strong and wideband.

4.2. Analog filterbank

An *analog filterbank* is just what its name implies: a bank (or collection) of analog filters. The analog filters are designed to pass through different ranges of frequencies. The power of the analog filters' output is measured and recorded. By creating a bank of filters with adjacent and non-overlapping passband frequencies one can get a complete picture of the input signal's spectrum.

Analog filterbanks can offer very wide bandwidths, but design of very narrow-band filters is challenging. Additionally, the input signal must be split multiple times, and each time the signal is split, its power is halved. Unlike digital systems, the shape and gain of each filter may differ. For these reasons, analog filterbanks are uncommon in modern radio astronomy.

4.3. Analog autocorrelator spectrometers

An analog ACS uses analog circuitry to implement multipliers and propagation times through carefully constructed delay lines to implement the desired tap delays. Details of specific scientific deployments of analog autocorrelation spectrometers can be found in⁶ and⁸.

The main advantage of the analog autocorrelator over its digital counterpart (Sec. 3.1) is that digitization need only take place at a rate commensurate with the averaging period of the correlator, rather than the bandwidth of the input signals. For this reason, analog autocorrelation spectrometers are usually seen in systems that have instantaneous bandwidths of many gigahertz which cannot be readily digitized by commercially available ADCs. In contrast, the number of physical components required scales with the number of channels, making analog ACS systems with many channels — readily implemented by digital systems — infeasible.

5. Design considerations and examples**5.1. Calibration requirements**

Dicke switching and calibration.

* Multibeam spectrometer systems

5.8. Example implementations

* HIPSR * Effelsberg? * Breakthrough listen

6. Conclusions

Polyphase filterbanks have attractive characteristics for radio astronomy applications. They offer excellent interchannel isolation and can be implemented using efficient FFT based structures. Field Programmable Gate Arrays are a viable platform on which to implement wide bandwidth polyphase filterbank spectrometers. I have implemented such a spectrometer using the Xilinx toolflow and CASPER block libraries. In this chapter I detailed the implementation and presented results on its performance.

7. Acknowledgements

The authors thank members of the CASPER collaboration for sharing their extensive knowledge with the wider community. D. Price thanks J. Moran for thorough discussion and debate on the virtues of polyphase filterbanks.
